Abstract: The paper presents numerical verification and experimental results for the set-point control of the nonholonomic mobile robot. The task is to move to the goal and reach it with desired orientation avoiding collisions with static obstacles. The obstacles in the task space are modelled using analytic functions. The algorithm is investigated for both convex and non-convex star-shape obstacles.

Keywords: nonholonomic mobile robot; collision avoidance; navigation function; set-point control

1 Introduction

In the mid-1980s Khatib [1] presented a crucial idea of using repulsive and attractive interactions to avoid collision with obstacles and move to a set goal. This approach utilized local artificial potential functions (APF) associated with the obstacles and the goal. Local minima were at a significant disadvantage using this method.

In 1990 Rimon and Koditschek in series of publications [3], [4], [5], [6] proposed a navigation function that is a global artificial potential function without local minima. This method was applicable for a variety of task space configurations: sphere worlds, star worlds and trees of stars. The shapes of the obstacles and also the shape of the task space are described by analytic functions. The free space (task space) remains after all obstacles have been removed from the workspace. It must be emphasized that even in the case of the properly designed navigation function there still remain saddle points and their number is equal to the number of the obstacles.
In 2004 Urakubo [2] proposed an extension of the above approach. In this method nonholonomic constraints of the differentially driven mobile robot are taken into account. Urakubo also introduced methodology based on the time-varying functions such that the robot leaves the saddle point.

In the next years the navigation function was used to control multi-robot systems [8], [9], [10], [11]. In all of them robots are treated as obstacles. Problems of conflicts resolution between agents, limited knowledge of the environment and nonholonomic constraints of mobile platforms are addressed in these papers.

Another approach for collision-free control of nonholonomic mobile robot was proposed in [13]. The algorithm does not require the map of the environment. An iteratively generated path is optimized in free space (the curvature of the path) and replanning is done in the case of an unpredictable drift. The algorithm was verified numerically.

Algorithms that decompose the free space into subsets is another class of methods. In [14] the nonholonomic robot is driven through a sequence of triangular cells. This method was verified experimentally with process noise and both static and dynamic environments with obstacles.

In this paper simulation and experimental results for the algorithm presented in [2] are shown. According to the author's best knowledge this method has not been previously verified experimentally. In comparison to the original publication the effectiveness of the algorithm was investigated not only for a convex but also for non-convex obstacles.

It should be mentioned that local artificial potential functions can also be used to solve complex collision avoidance problems [7] in the case of circular obstacles; however, they must be designed carefully to avoid local minima.

In Section 2 the kinematic model of the robot and control algorithm introduced in [2] are presented. In Section 3 simulation results are shown. Section 4 briefly describes the experimental test-bed and experiments. Finally, the paper finishes off with concluding remarks.

\section{Control Algorithm}

The model of the differentially driven mobile robot is given by the following equation:

\begin{equation}
\begin{bmatrix}
\dot{x} \\
\dot{y} \\
\dot{\theta}
\end{bmatrix} = B
\begin{bmatrix}
v \\
\omega
\end{bmatrix}
\end{equation}
where $x$, $y$ and $\theta$ are position and orientation coordinates of the robot respectively, $u = [v \omega]^T$ is control vector with $v$ denoting linear velocity control and $\omega$ - angular velocity control of the mobile platform and

$$B = \begin{bmatrix} \cos \theta & 0 \\ \sin \theta & 0 \\ 0 & 1 \end{bmatrix}.$$  \hfill (2)

Control proposed in [2] is given by the following equation:

$$\begin{bmatrix} v \\ \omega \end{bmatrix} = - \left( a \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} + b \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix} \right) B^T \nabla V$$  \hfill (3)

where

$$b = -\bar{b} \frac{L^T \nabla V}{h(g)}$$  \hfill (4)

and $\nabla V$ denotes the gradient of the artificial potential function, $L = \begin{bmatrix} \sin \theta - \cos \theta & 0 \end{bmatrix}^T$, $h(g) = g^2 + \epsilon_g \sqrt{g}$. $g = \|B^T \nabla V\|$. In the above equations $a$, $\bar{b}$ and $\epsilon_g$ are positive parameters.

The navigation function is given by the following equation:

$$V = \frac{C}{C^\kappa + \beta},$$  \hfill (5)

where $C = \|\dot{r}\|^2 + w\theta^2$, $w = \frac{k_w}{k_w + \|\dot{r}\|^2}$; $k_w$ is a positive parameter that allows tuning the weight of orientation when the robot approaches the desired position.

As noted in [4] by setting a sufficiently large value of $\kappa$ it is ensured that (4) is a navigation function i.e. there are no local minima in the APF.

To solve the problem of local minima for the case of star shape obstacles position coordinates of the robot $r = [x \ y]^T$ are transformed to the model sphere world as follows:

$$\hat{r} = \left( 1 - \sum s_i(r) \right) r + \sum s_i(r) I_i(r)$$  \hfill (5)

where $M$ - number of the obstacles, $r = [x \ y]^T$. 

-125-
\[ s_i(r) = \frac{||r||^2 \prod \beta_j(r)}{||r||^2 \prod \beta_j(r) + \hat{\lambda} \beta_i(r)} \]  

and

\[ T_i(r) = \frac{\rho_i(1 + \beta_i(r))(r - q_i)}{||r - q_i||} + p_i \]

\[ T_0(r) = \frac{\rho_0(1 - \beta_0(r))(r - q_0)}{||r - q_0||} + p_0 \]

In the above equations \( p_0, p_i \) represent the centers of the spheres to which original obstacles are transformed \( \rho_0, \rho_i \) are their radii, \( q_0, q_i \) are the centers of the stars (points from which all the rays cross the boundary of the obstacle once and only once) and \( \beta_0, \beta_i \) are analytic obstacle functions.

The sphere-world obstacle function is a product of the sphere obstacle functions:

\[ \hat{\beta} = \prod_{i=0}^{M} \hat{\beta}_i \]

where

\[ \hat{\beta}_i(\hat{r}) = ||\hat{r} - p_i||^2 - \rho_i^2 \]

\[ \hat{\beta}_0(\hat{r}) = \rho_0^2 - ||\hat{r} - p_0||^2 \]

3 Simulations Results

Simulation results were obtained for the task space containing one circular obstacle and one star-shape obstacle. The origin is the desired position and the desired orientation is equal to zero.

As the navigation function (4) is the function of three variables it is not possible to show its graph. In Figs. 1a and 2a the x-y plane cross-sections of \( V \) for \( \theta = 0 \) and \( \theta = \pi / 2 \) are shown, respectively. It can be observed that in the first case the global minimum exists in the center of the task space. In the second one the potential grows around the origin not allowing the robot to approach it with incorrect orientation. If the robot is too close it is repelled, but as the orientation...
converge to the desired value the x-y components of the V drive robot to the origin.

**Figure 1a**  
APF for $\theta = 0$

![Figure 1b](image2.png)  
**Figure 1b**  
Control vector field $-\nabla V$ for $\theta = 0$

In Figs. 1b and 2b x-y plane cross-sections of the $-\nabla V$ for the same robot angles are shown (the length of the vectors was normalized).

The data were obtained for the following values of the parameters: $a = 0.25$, $b = 1.25$, $\varepsilon_g = 10^{-6}$, $\kappa = 3$, $k_w = 0.1$, $\lambda_s = 10^6$.

In Fig. 3 the robot path in x-y plane is shown. The dashed line represents simulation results and solid line experimental data (their comparison will be discussed in the next section). The initial coordinates of the robot were as follows

$$[x \quad y \quad \theta]^T = [-1.01 \quad 0.92 \quad -2.92]^T.$$

![Figure 2a](image3.png)  
**Figure 2a**  
APF for $\theta = \pi/2$

![Figure 2b](image4.png)  
**Figure 2b**  
Control vector field $-\nabla V$ for $\theta = \pi/2$
In Fig. 4a time graphs of the position errors \( e_x \) - solid line, \( e_y \) - dashed line) and orientation errors \( e_{\theta} \) - dot line) are shown. They converge to zero reaching small values in about 30 seconds.
In Fig. 5a linear (solid line) and angular (dashed line) controls for the robot are presented.

Fig. 6a presents wheel control velocities (\(\omega_R\) - solid line, \(\omega_L\) - dashed line). There are peaks of the large values that cannot be achieved in the physical system. In the experiments presented in the next section these values are limited to achievable values.

In Fig. 7 robots path in x-y plane for a more complex case is shown. To reach the desired coordinates robot has to bypass the “leaf” of the obstacles. For this case local APF control algorithm usually fails trapping the robot in the local minimum. The initial coordinates of the robot were as follows

\[
\begin{bmatrix}
  x \\
  y \\
  \theta
\end{bmatrix}^T = \begin{bmatrix}
  1.22 \\
  0.65 \\
  -0.51
\end{bmatrix}^T.
\]
In Fig. 8a position and orientation errors are presented, while Fig. 9a shows platform control signals. In Fig. 10a wheel control graphs are plotted.
4 Experiments

4.1 Experimental Test-Bed

The algorithm was verified experimentally using the MTracker robot (Fig. 11). The MTracker is a differentially driven mobile robot. Its diameter is 170 mm and the height (in common configuration) – 65 mm. The linear velocity can reach the value of 1 m/s. The low level motion controller is implemented with the signal processor TMS 320F28335 150 MHz. Presented results were obtained using a robot expanded with Intel Atom 1,6 GHz PC board and Wi-Fi link used to obtain localization data from the external vision system. The robot was equipped with an LED marker for reliable and fast visual recognition. More details about the test-bed including robot configuration, communication and localization system can be found in [12].
4.2 Experiments

In Fig. 3 path of the robot in x-y plane is presented. The experimental data are represented with a solid line. As can be observed in the figure both simulation and experimental results are very similar. In this experiment robot moves in open areas of the environment but it is required to change the orientation. As it approaches the origin the direction of the motion is changed four times to drive the orientation according to the control rule.

In Fig. 4b position and orientation errors are shown. They reach near zero values in 35 seconds.

In Fig. 5b platform control signals are shown. There are peaks that are not achievable in the real system. In Fig. 6b wheel controls are presented. They are limited (\( \omega_{RL,\text{max}} = 9 \text{rad/s} \)) and scaled to keep the robot on the path. Limitation and scaling of the wheel velocities is the best solution of the large control signal problem as it is not affecting the mobile platform direction vector (it affects only its evolution in time). This approach separates a high level controller; whose primary objective is to avoid collisions, from the problems connected with the physical actuator limitations.

In Fig. 7 both simulation and experimental results for the star bypassing case are shown. The solid line represents the experimental path of the robot in the x-y plane and dashed line represents the simulation data. As can be observed in the figures in simulation the robot changed the direction of motion three times. In the experiment one more motion direction change was performed. Which was due to the disturbances and/or delays in the positioning system, however both graphs are very similar.
In Fig. 8b position and orientation errors are presented. They reach the near zero value in about 60 seconds (in simulation 40 seconds).

In Fig. 9b and 10b control signals for the platform and wheels are shown respectively. As in the previous experiment wheel velocities were limited and scaled.

Conclusions

Simulation and experimental results for navigation function control were presented. The non-convex star shape obstacle makes presented cases nontrivial. As shown in the attached figures the nonholonomic mobile robot reaches the desired position and orientation avoiding collisions with both convex and non-convex obstacles.

List of notations

- \( x, y \) - position coordinates of the robot
- \( \theta \) - orientation of the robot
- \( v \) - linear velocity control
- \( \omega \) - angular velocity control
- \( B \) - zero space of the Pfaffian matrix
- \( a, b, \varepsilon_g, \kappa, k_w, \lambda_s \) - positive constant parameters
- \( V \) - navigation function
- \( \nabla V \) - gradient of the navigation function
- \( b \) - is defined by Eq. (4); is a weighting coefficient of the skew symmetric matrix
- \( L \) - Pfaffian matrix
- \( g \) - norm of the product zero space matrix and gradient of the navigation function
- \( h(g) \) - nonlinear function of \( g \); used as coefficient in Eq. (4)
- \( C, w \) - positive coefficients used to define Eq. (5)
- \( r \) - robot position
- \( \hat{r} \) - robot position in the auxiliary sphere world
- \( \beta \) - product of all obstacle functions
- \( \beta_i \) - obstacle function associated with the \( i \)-th obstacle
- \( s_i, T_i \) - auxiliary variable for star-to-sphere transformation
\( p_i \) - center of the \( i \)-th sphere

\( \rho_i \) - radius of the \( i \)-th sphere,

\( q_i \) - center of the \( i \)-th star,

\( M \) - number of the internal obstacles,

\( e_x, e_y, e_{\theta} \) - coordinate errors,

\( \omega_R, \omega_L \) - wheel velocities,

\( \omega_{RL,\text{max}} \) - wheel velocity limit.
